ABSTRACT

The highest concentration of Palaeolithic sites known in the Iberian Peninsula is located in the lower stretches of the Manzanares and Jarama rivers. This area, together with a number of zones in the Tagus valley, constitutes one of the most important archives for the knowledge of the European Pleistocene. The purpose of this paper is to establish the chronological frame and the technological strategies implemented in manufacturing lithic tools during the Acheulean techno-complex in the middle stretch of the Tagus basin. Use of large flakes for making bifaces is common in the Acheulean assemblages from this area, as well as in the rest of the Iberian Peninsula and the south of France.

The earliest Acheulean evidence has been dated to between MIS 15 and MIS 13. From MIS 11/MIS 9 on, this techno-complex is widespread in the region, until MIS 6, when the last evidence has been recorded. Handaxes, cleavers on flake and trihedral picks dominate in the chaînes opératoires of façonnage, which are present in significant percentages. Short chaînes opératoires of débitage prevail in quartzite, and discoid and polyhedral in flint. Most retouched tools are seldom elaborate. Lithic assemblages with chaînes opératoires of façonnage exclusively represented by handaxes start to be recorded towards the end of the Middle Pleistocene. These handaxes are more elaborate than previous and the retouched tools are more complex.

Among the activities identified in the sites excavated in overbank facies, exploitation of large mammals, particularly proboscideans, is outstanding, as well as the manufacture of lithic tools and the exploitation of primary flint outcrops. The recording of long recurrent settlements on the same location is remarkable.

1. Introduction

The beginning of the Acheulean period in Europe is still being debated (Moncel et al., 2016; Mosquera et al., 2016). In Southern Europe it is recorded since at least MIS 12, although older dates have been published for sites belonging to this techno-complex (Falguéres et al., 2004; Barsky and de Lumley, 2010; Lefèvre et al., 2010; Moncel et al., 2013; Pereira et al., 2015). However, confirmation of these dates by alternative dating methods would be desirable (Demuro et al., 2014). In other cases, the Acheulean character of the lithic industry is not decisive enough for corroboration (Valderdú et al., 2014; Santonja et al., 2016).

The diversity of technological strategies in the manufacturing of lithic tools, particularly handaxes, has prompted some authors to allude to “Acheuleans” rather than a single Acheulean period in Western Europe (Moncel et al., 2016). The Acheulean in the Iberian Peninsula and the south of France shows certain technological characteristics in common with the African Acheulean, which are not found in the rest of Europe (Clark, 1994; Sharon, 2010). This suggests possible connections with North Africa via the Strait of
Gibraltar (Santonja and Villa, 2006; Dorianichev and Golovanova, 2010; Sharon, 2011; Bar-Yosef and Belfer-Cohen, 2013).

The most characteristic morphotypes of the Acheulean, handaxes, cleavers, and picks, are frequently made on large flakes in Africa (Roche et al., 2003; Semaw et al., 2009). Production of these blanks has been considered one of the most important features of this techno-complex (Isaac, 1969; Leakey, 1975). The “large flake” definition of Kleindienst (1962), as one larger than 10 cm, has been accepted by most researchers. In Europe, the use of large flakes for bifaces is common only in the Iberian Peninsula (Santonja and Pérez-González, 2010) and in the basins of the rivers Garonne, Rhône, Roussillon and Tarn, in Southern France (Tavoso, 1986; Mourre, 2003; Turq et al., 2010). The availability of coarse grained rocks, combined with the presence of appropriate -blanks, as sometimes occurs in the Iberian Peninsula and Southern France, has been considered as the key factor concerning this distinction. However, large flakes can also be knapped from fine-grained rocks (Rolland, 1995; Sharon, 2010), as occurs at sites such as La Noira (Moncel et al., 2016), or at Caune de l’Arago, levels P and Q (Barky and Lumley, 2010; Barsky, 2013). However, only a few of these were used for manufacturing handaxes and cleavers.

Since the end of the Lower Pleistocene, lithic assemblages composed of cores and flakes have been recorded in Europe (Parfitt et al., 2010; Turq et al., 2010; Jiménez-Arenas et al., 2011; Toro et al., 2011; Ollé et al., 2013). These industries could actually be the substratum of the European Ancient Middle Palaeolithic (EAMP), which has been recorded in the continent since the final MIS 9 or early MIS 8 (Moncel et al., 2005; Bourguignon et al., 2008; Koehler, 2008; Richter, 2011; Santonja et al., 2016). Therefore, in Europe, the earliest Acheulean coexisted with flake and core industries which existed on the continent since the final Lower Pleistocene, and later, since the end of MIS 9, with EAMP. As a result of this coexistence, the European lithic assemblages developed between MIS 8 and MIS 6 show different technological solutions derived from mutual influences (Santonja et al., 2016).

In the middle stretch of the Tagus basin, as in the rest of the Meseta of the Iberian Peninsula (Santonja and Pérez-González, 2010), using large flakes for manufacturing bifaces is a common practice from the first to the last examples of the Acheulean, regardless the availability of coarse-grained rocks, although access to these raw materials can be noticed from its proportional representation. The purpose of this paper is to identify the timeframe and the technological strategies used in manufacturing lithic tools during the Acheulean techno-complex in the middle stretch of the Tagus basin.

The highest density of Palaeolithic archaeological sites known in the Iberian Peninsula lies within the fluvial deposits of the last stretch of the Manzanares and Jarama rivers, as well as in some areas of the Tagus valley (Fig. 1) (Rubio-Jara et al., 2002). This is due on the one hand to the geological characteristics of these valleys, and on the other hand to modern day demand for aggregates in Madrid, which have favoured first the accumulation of Pleistocene deposits, and then access to large sections of those deposits in sand and gravel quarries (Rubio-Jara et al., 1999; Santonja and Vega, 2002).

The Pleistocene at the Tagus basin has been studied since 1850, when two elephants were excavated in Tejar de las Animas, at Cerro de San Isidro in Madrid (Paz Graells, 1897; Santonja et al., 2001). Shortly after, the first knapped lithic artifacts were recognized, including a flint cleaver, which were published in 1863 (Vermeulin and Larret, 1863). Between 1917 and 1931, under the initiative and supervision of Hugo Obermaier (1879-1946), several sites were discovered and investigated (Obermaier, 1925). These works were carried out during the 1950’s and 1960’s, with an approach distant from the accepted premises of the time, although with certain international repercussion thanks to the 4th International Congress of Prehistoric and Protohistoric Sciences and the 5th International Quaternary Congress (INQUA), which were held in Madrid in 1954 and 1957 respectively. From 1970 there was a renewal of Palaeolithic research, but despite the innovative approaches (Santonja et al., 1980), the 20th century ended with disappointing results regarding the knowledge of this period.

During the first decade of the current century, data regarding Pleistocene human occupation in this area has been significantly updated. Since the late nineties, systematic research projects have been implemented in the middle and lower stretches of the Jarama and Manzanares rivers (Uribelarrea, 2008; Panera, 2009; Rubio-Jara, 2011), as well as in their interfluve (Bárez et al., 2010; Baena Preysier et al., 2015), and in the middle stretch of the Tagus river (Rodríguez de Tembleque, 2008, 2010; López-Recio et al., 2015). The research programs carried out during the last years in the Manzanares and Jarama valleys, as well as in the Tagus valley, are considered as regional studies of the Pleistocene. They have been based on systematic field surveys on sections of fluvial deposits, where a large number of industrial assemblages have been recorded in stratigraphical context. Many of them in gravel bars, and others on overbank facies. Finally, a series of numerical dates have updated the general knowledge of the Pleistocene in the South Submeseta of the Iberian Peninsula, in particular the Acheulean, which has highlighted this area as one of the most important European archives for the knowledge of this period.

The lithic industries found in stratigraphy in Pleistocene fluvial deposits of the low stretches of the rivers Manzanares and Jarama valleys, and between the mouth of the river Algodor and Puente del Arzobispo in the river Tagus valley (Fig. 1), are described in this paper, based on their geomorphological and chronological frameworks. In this paper we shall use the term bifaces (handaxes, cleavers and trihedral picks) in the context of current knowledge about the Acheulean, as it has been recently considered by several scholars (cf. Diez-Martín and Eren, 2012: 325 ff.; Sahnnouni et al., 2013: 309 ff. and references therein).

2. Geomorphology and chronostratigraphic sequence of the terraces at the Tagus, Jarama and Manzanares rivers

The Tagus basin is located within the South Sub-Meseta of the Iberian Peninsula. It is bounded by the Sistema Central (Gredos and Guadarrama mountains) to the north, by the Cordillera Ibérica to the east, and by Montes de Toledo to the south.

The geological uniqueness of part of the valleys of the Tajo, Jarama and Manzanares rivers has contributed to the preservation of lithic industry and faunal remains from the Pleistocene. These valleys are characterised by the development of a great number of fluvial terraces, related to Quaternary climatic oscillations; technocultures (Alía, 1960; Pérez-González, 1980; Silva et al., 1988a,b; Pérez-González, 1994), isostatic rising and blocks adjustment, and lithological structural controls (Pérez-González, 1971), which were responsible for their configuration.

In the Tagus valley, near the city of Toledo, 12 terrace levels have been distinguished (Pérez-González, 1994; Roquero et al., 1999) between +4–6 m and +125 m. Upstream from Toledo, in Aranjuez, karstification of the Miocene evaporite-gypsum has led to the thickening of the fluvial terraces (Pérez-González, 1971).

In the high-middle trench of the Jarama valley, 19 terrace levels have been recorded between +3–5 m and +190 m (Fig. 2). In the lower part of the valley, Miocene evaporite-gypsum, which crop-out to the east and south of Madrid, have facilitated syneformational subsidence processes in the underlying karst, affecting terraces with a relative level lower than +40 m. These terraces, which upstream are of stepped and perched types, overlap the oldest ones, giving rise
to the Complex Terrace of Arganda (hereafter CTA) (Pérez-González, 1971, 1994; Panera et al., 2011), over which the current floodplain is set (Figs. 1 and 2). CTA is made up of successively stacked fluvial sequences, named from bottom to top Arganda I, II, III, which match up with terraces +30–32 m, +23–24 m, and +18–20 m respectively (Pérez-González and Uribelarrea, 2002; Panera et al., 2011). Arganda I contains several floodplain deposits, whereas Arganda II and III consist mainly of sand and gravel bars matching channel facies. Finally, Arganda IV is made up of fluvial fan deposits which can exceed 20 m in thickness, and originate in the oldest Miocene and Quaternary relieves from the left margin of the Jarama River, also prone to contain in situ archaeological sites (Panera et al., 2005).

In the Manzanares valley, upstream from Madrid, 13 terrace levels have been recorded between +4–5 m and +95 m (Pérez-González, 1994). This system of stepped terraces gives way to a system of complex terraces, named Complex Terrace of Butarque (hereafter CTB) (Goy et al., 1989). The terraces formed over evaporitic rocks +25–30 m, +18–20 m and +12–15 m, are overlapped and affected by the syndepositional subsidence, resulting in a huge thickness increase of dozens of meters. Silva (2003) names this as the Manzanares Complex Terrace (TCMZ).

The chronostratigraphy of these fluvial valleys has been established by radiometric dates of the terrace sequences combined with palaeomagnetism, biochronological and numerical data. The terrace +75–80 m (Salto de la Zorra), in the Tagus valley, contains Equus stenonis (Alferez, 1978, 1999), and belongs to the final Lower Pleistocene stage, before the Cromerien stage (Aguirre, 1989). A mandible of a Mammutthus meridionalis, of Lower Pleistocene date was found at the terrace +60–65 m, in Valdelobos Superior (Alfrez, 1977, 1999). This is consistent with the recorded reverse polarity, which has been interpreted (Pinilla et al., 1995) as belonging to Chron Matuyama. In the Jarama valley, the Brunhes–Matuyama reversal (0.780 Ma ago), took place after the last marine isotopic stadia 9 and 7. The terrace +60–67 m, which shows reverse polarity (Benito-Calvo et al., 2008), has been dated by ESR (Electron Spin Resonance) to at least 0.780 Ma (Moreno et al., 2012), whereas a terrace +50–54 m with normal polarity (Benito-Calvo et al., 2008) has been dated by ESR to 0.670 Ma (Moreno et al., 2012).

In the terrace +40–45 m of the Tagus River, an assemblage of macro and micromammals characteristic of the Middle Pleistocene was found (Alfrez, 1977, 1999; Sese et al., 2000, 2010). The terrace +25–30 m has been dated by IRSL (post-Infrared Stimulated Luminescence) and AAR (Amino Acid Racemisation) (Lopez-Reccio et al., 2015). The dates obtained by IRSL applied on feldspar K grains are >280 ka and 292 ± 17 ka respectively, whereas the AAR date, taken from three Equus molaris, provides a date of 226 ± 37 ka, in Pinedo, suggesting that the fluvial deposits of the terrace +25–30 m were laid between the isotopic stadia 9 and 7.

In the Jarama valley, the evolutionary stage of micromammals from Arídos I –in the Unit Arganda I of CTA (±T +30–32 m) (López Martínez, 1980; Santonja et al., 1980), suggests a Late-Middle, but not Final Pleistocene date. This is consistent with two dates obtained by AAR, which suggest a period between 254 ka and 425 ka (379 ± 45 and 332 ± 30 ka), overlapping with the final stretch of MIS 11, between 335 ka and 370 ka (Panera et al., 2011). In the Arganda II Unit (±T +23–24 m), the micromammal assemblage from Valdocarros (Sese et al., 2011) places this unit some time later than Arídos I, in the Late Middle Pleistocene. AAR analysis applied to two samples taken from two consecutive flood sequences provides dates of 262 ± 68 ka and 254 ± 47 ka respectively, overlapping with the period between 255 ka and 269 ka (Panera et al., 2011). Biostratigraphic and numerical dates have not been retrieved from the Arganda III Unit (±T +18–20 m) due to the high cementation characteristic of this deposit. Aluvial deposits from Arganda IV have been dated by OSL (Optically Stimulated Luminescence) between 112 ± 36–22 ka and 8 ± 0.7 ka (Panera et al., 2005, 2011). Taking into consideration on the one hand the climatic needs of micro-mammals and herpetofauna from Arídos 1, Valdocarros and HAT (Arganda I, II and IV respectively), characteristic of mild climate (Blain et al., 2012), and on the other hand the overlapping of the available numerical dates, Arganda I falls within the late MIS 11 or early MIS 9; Arganda II would match some interstadial period from MIS 8 (although late MIS 9 or early MIS 7 should not be ruled out), and the basal third of Arganda IV, downstream from Valdocarros, would match with Is 20 of MIS 5a, although some parts (such as the top) could be dated to the Early Holocene (Panera et al., 2011).

Remains of Praedama sp. (the same as Megaloceros according to Lister, 1994 and Made, 2001) were found in Transfesa/Tafesa, in the T +20–30 m, in the Manzanares valley. These remains, together with other species of large herbivores (Praedama antiquus and Praedama savini), suggest this site dates to around the Biharianse-Oldenburgse time limit (MIS 11–13; Sese and Soto, 2000). Regarding Tafesa, Mazo (2010) dates this site before MIS 11, due to the presence of Megaloceros savini, which is chronologically earlier than Megaloceros giganteus, and is recorded in MIS 11 (Lister, 1994; Made, 2001). There are neither numerical dates nor biostratigraphical data for terraces T +35–40 m and T +18–20 m of the River Manzanares. The CTB could be composed of at least T +18–20 m and +12–15 m. This deposit can reach up to 70 m (Uribelarraea, 2008), although only 15 m are visible, dated between the Final Middle Pleistocene and MIS 4. A minimum date of 125 ka has been obtained by TL for the bottom of the CTB, at the beginning of this unit, in sequence 3 of Estanque de Tormentas de Butarque (ETB) (Dominguez et al., 2007, 2009). There are two TL dates for sequence 2 of ETB, 78.7 + 10.7/–9.7 ka BP and 84.6 + 12.6/–11.2 ka BP (De los Arcos et al., 2008; De los Arcos et al., 2010). These would be minimum dates, according to the biochronological data provided by the association of microfauna and the evolutionary stage of Microtus brevicaudus, which suggests a date in the last quarter of the Middle Pleistocene (Laplaneta et al., 2015). In Los Estragales 1, there are two TL dates for the visible bottom of CTB, overlapping between 111.1 y los 133.3 ka (Pérez-González et al., 2008). In EDAR Culebro 1, there is one date obtained by OSL of 120.541 ± 6.851 ka, and another one obtained by AAR, which stretches between 133 ± 28 and 105 ± 10 ka (Manzano et al., 2010). Two further dates, of 133 ka and 134 ka, were obtained by TL in the Arriaga sand quarry (Silva et al., 2012). In Arriaga I, an association of microfauna with the presence of Microtus brevicaudus has been recorded, thus dating this site to the Final Middle Pleistocene (Sese and Lopez-Martinez, 2013). However, other researchers (Laplaneta et al., 2015) consider the remains to be Microtus cabrerae, belonging to the Upper Pleistocene. Nonetheless, the lack of biometrical data of the Iberomys (Microtus) lineage towards the end of the Middle and beginning of the Upper Pleistocene means that a date in the Late Middle Pleistocene has not been completely ruled out. The middle stretches of the outcrop of the CTB recorded at PRERESA, dated to 85.3 ± 4.7 ka and 84.1 ± 5.6 ka (Yravedra et al., 2012; Panera et al., 2014) belong to MIS 5b-5a; and so does Los Estragales 2, dated to 90.6 ± 9.1 ka (Pérez-González et al., 2008). Finally, the apparently non-eroded tops of CTB, are dated to 64.5 ± 15.2/–11.3 and 60.1 ± 3.4 ka in Los Estragales (Pérez-González et al., 2008). T +12–15 m, which is overlapped and entrenched within the CTB in its initial stretch, has provided two
Fig. 1. A. Location of the Tajo basin, Iberian Peninsula. B. Sites cited in text of the Tagus, Jarama and Manzanares valleys. C. Geological sketch of the rivers Jarama and Manzanares. numerical dates, one of 40 ± 2.7 ka (Pérez-González et al., 2008), and another one 40.2 ± 4.6 ka (Domínguez et al., 2007, 2009).

3. The Acheulean in the Tagus basin

3.1. Human presence before MIS 13: the first Acheulean traces

No site from this period has ever been excavated. The information available derives from intensive surveys carried out on stratigraphical sections. The scant finds of lithic industry have been located in the middle and high terraces of the River Tagus and in some of its tributary rivers on the left bank, within the stretch of the basin between the mouth of the River Algodor and the town Puente del Arzobispo (Santonja and Pérez-González, 1997, 2000–2001; Rodríguez de Tembleque, 2008, Rodríguez de Tembleque et al., 2010).

The oldest remains have been recorded in T + 105 m of the River Tagus, at Montalvo (La Pueblanueva), where a chopper, an exhausted core and a flake fragment were found (Santonja and Pérez-González, 1997). Two large retouched flakes and two large quartzite scrapers were found in the T + 83 m of the River Pusa (at El Castillo, Belvis de la Jara). Lithic industry has been discovered at several locations with similar stratigraphical position in the terrace T +75–80 m of the River Tagus and its affluents (Rodríguez de Tembleque et al., 2010). At El Espinar (Almonacid del Tajo), two choppers and one denticulate were found in a level of gravel (Santonja, 1981a,b; Santonja and Querol, 1982; Santonja and Pérez-González, 2000–2001), as well as two simple flakes, one multifacial core, one quartzite bec and another retouched item (Rodríguez de Tembleque et al., 2010). Downstream from Toledo, in Salto de la Zorra, remains of Equus stenonis (Cocchi, 1977, 1978) have been recorded, as well as three quartzite flakes—one of which is retouched—, one retouched flint flake and a further nine pieces which were unclearly knapped. Finally, three unifacial quartzite cores—of which one was quite large and another one bipolar—were found at Quinto de Ochavo (Talavera de la Reina) (Rodríguez de Tembleque et al., 2010). These may indeed be the first properly contextualized remains of human occupation in a fluvial environment in the Meseta, and should be dated within the lower Pleistocene (between 1.3 and 0.9 Ma). In all cases, these are small assemblages (no more than ten pieces), except for the quartzite pieces, showing pronounced fluvial rolling and doubtful in many cases.

Fig. 2. Terrace sequences from the Tagus, Jarama and Manzanares rivers with indication of the relative altitude in m, in reference with the main channel (S.R., Sangrera river; T.S., Tamujoso Steream). Sites cited in text: 2, Aridos 1 and 2; 4, Cañete; 6, Dehesa de Cobisa; 7, El Cañaveral; 8, El Castillo; 11, Hornaguera and Pandera; 12, La Casa del Guarda; 15, Las Acacias; 17, Los Abiones; 18, Sangrera; 19, Montalvo; 20, Orcasitas; 21, Oxígeno; 22, Paredera de la Mata; 23, Povedo; 24, Polígono Industrial de Toledo; 26, Puente Pino; 27, Téllez inferior; 28, Salto de la Zorra; 29, San Isidro; 30, Santa Elena; 31, Tamujoso; 32, Quinto de Ochavo; 33, Transfesa/Tafesa; 34, Valdocarros; 35, Gelves; Paleomagnetic data, relevant mammal, and numerical dates (BP × 1000): IRSL (post-Infrared Stimulated Luminiscence), AAR (Amino Acid Racemisation), OSL (Optically Stimulated Luminescence), TL (Thermoluminescence); Technocomplex: Ach (Acheulean), M.P. (Middle Palaeolithic).
In the terraces of the Tagus valley, lithic industry has been recorded in practically all levels comprised between +80 m and +50 m, both relative levels included, although scarce and, with exceptions, showing moderate to pronounced fluvial wear (Rodríguez de Tembleque, 2008; Rodríguez de Tembleque et al., 2010). There are also few pieces per level, nearly all made of quartzite, mainly flakes and cores. In T +70 m of the stream Tamujoso (afluent of the River Gébalo on its left bank, which joins the River Tagus), seven quartzite pieces have been recorded, five of which have been clearly stratigraphically located. These include a multifacial core, three flakes and one biface on flake with measurements of 114 x 85 x 40 mm (Figs. 1 and 2), which could actually be the first evidence of the Acheulean in the Tagus basin (Rodríguez de Tembleque et al., 2010). Furthermore, discoid cores, one nucleiform handaxe and several tools on flake are included among the 18 pieces found at the T +60–65 m of River Sangrera (Santonja and Pérez-González, 2000–2001), in San Bartalomé de las Abiertas (downstream Talavera de la Reina).

In the Jarama valley -T +55–60 m– 33 pieces have been documented. Bifaces have not been identified among them, but discoid, bifacial, orthogonal multifacial and kombewa cores have been recorded (Panera, 2009).

Lithic industry within a stratigraphical context has been recorded at different locations within the terrace +40–45 m of the River Tagus. These terrace levels may correspond with MIS 15–12 (see discussion). Dozens of pieces showing clear Acheulean features have been recovered from Hornaguera and Paridera (Malpica de Tajo) (Santonja and Pérez-González, 1997; Rodríguez de Tembleque, 2008). Most were made of quartzite. The assemblage is composed mainly of unretouched flakes; also cores, including one outstanding example from which supports for cleavers were detached; one chopper, one cleaver on flake, one trihedral pick and a thick ovate handaxe-Lithic industry in stratigraphical context was recorded during the excavation of a skull of Mammutthus trogontherii close to the Toledo Industrial Estate (Santonja, 1981a; Santonja and Querol, 1982; Santonja and Pérez-González, 2000–2001). Also, in Buenavista inferior and Salchicha inferior chopping tools (Santonja, 1981a) and some trihedral pick and handaxes (Alferez, 1977) have been recorded. In other similar terraces, an Acheulean-looking industry has been recorded, although with small numbers of pieces, as in the Gébalo and Tagus valleys, both in the area of Talavera de la Reina (Las Estacas, Cerro de Miralobos, etc.), and in La Puebla de Montalbán (Rodríguez de Tembleque, 2008).

### 3.2. Lithic assemblages recorded between MIS 13 and MIS 6

#### 3.2.1. Terrace +35–40 m

The site of Puente Pino is related to this level, near Puente del Arzobispo, some few metres downstream the mouth of the River Uso. Two sites have been distinguished: Puente Pino TGS and PNA. TGS is located on the terrace +40 m of the River Tagus, associated with deposits of lateral channels which have eroded the terrace. It consists of a deposit of fluvial gravels sealed by a thick level of silt clay with inclusions of very fine eolic sand. PNA seems to be associated with deposits in a terrace +35 m, entrenched in the T +40 m of the River Tagus. The lithic assemblage lies over a deposit of fluvial sand and is covered by silt clay with very fine sand. Both levels show a high average density of Acheulean industry (Figs. 3 and 4); at least 70 pieces per m² in PNA, and about 477 pieces per m² in TGS (Rodríguez de Tembleque, 2004; Rodríguez de Tembleque, 2005a,b, 2008).

The lithic industry is made mainly of quartzite, but also contains quartz and to a lesser extent flint and other rocks. In both levels -but particularly in PNA-all the regular elements of the lithic production processes are represented in consistent proportions. Several types of tools have been documented: hammerstones, some flakes, debris, chunks, un-retouched and retouched flakes (scrapers, denticulates, backed knives, awls and so forth), cores, of which some have been apparently retouched, and nucleiform pieces sometimes with a trihedral point, choppers (mainly unifacial), cleavers on flake (types 0, 1 and II), handaxes of different types and sizes, sometimes partial, many of them knapped on flakes; and few trihedral picks, as well as multi-purpose tools. The multifacial type predominates among the cores, followed by the bifacial type, often showing centripetal removals and Levallois features. A significant number of the cores are elemental or simple, and others are exhausted or in a terminal phase of exploitation. Remarkable intensity in flaking and use of the cores can be inferred from the characteristics present in the flakes and progressive cores. Frequent use of large quartzite flakes for knapping bifaces is outstanding. Quartz, and especially flint industries are smaller in size than that made of quartzite, in accordance with the lower availability and smaller size of those raw materials. Bifaces made of quartz or flint have not been recorded.

#### 3.2.2. Terrace +25–30 m

The best-known site in the Tagus valley is Pinedo, in Toledo (Querol and Santonja, 1979). A lithic assemblage of some 5961 pieces was retrieved, as well as some faunal remains. All the remains were found in secondary positions and linked to channel bars (Díaz and Pérez-González, 1979), and were retrieved from 110 m³ of an area 25 m². The most common raw material is quartzite (68%), followed by flint (25%) and quartz (7%). It is inferred from this data that flint was either highly selected or brought to the site, as its presence in the gravel deposits is lower than 2% (Querol and Santonja, 1979). The industry shows moderate fluvial wear and is characterised by a minimal presence of Levallois flakes, an abundance of entame flakes, and a lack of Levallois cores, the most predominant being cores with multifacial and discoid schemes. The diversity of tools on flake is outstanding, scrapers being the predominant type. Among the macrotools, the chopper is the most abundant category, followed by trihedral picks, handaxes and cleavers on flake. With regard to the handaxes -all of which were made of quartzite except two of flint-thick ones prevail, with amygdaloid, firon or abbevillian silhouettes. They are poorly elaborated, which explains the high number of partial specimens and abbevillian types with asymmetric edges and silhouettes. The cleavers on flake barely show any retouch, and half show wear traces in their cutting edges. Straight edges predominate, as well as

![Fig. 3. Level PNA at Puente Pino during the excavation campaign in 2005.](image-url)
thick bases and Tixier’s 0 and I types (Querol and Santonja, 1979; Fig. 5).

Two sites have been recorded in the left bank of terrace +25–30 m of the River Tagus, both in road sections and gravel quarries. This is probably the same terrace as Pinedo, which is located about 10 km downstream and on the right bank. The sites are Cañete Bajo (Santonja and Pérez-González, 1997; 2000–2001; Rodríguez de Tembleque, 2008) and Cañete Alto (Rodríguez de Tembleque, 2008). Some faunal remains and Acheulean industry have been recorded in a secondary position, particularly in bed load deposits. These industries show densities, alterations and general characteristics similar to those from Pinedo. Two sedimentary units in a channel facies deposit have been distinguished in Cañete Bajo, or Cien Fanegas. Remains of E. (Paleoloxodon antiquus) were found in the bottom 5 m sand deposit, and 130 lithic pieces were retrieved from towards the top of the 3 m gravel deposit, all quartzite but six of flint, among which old industries were frequently used as blanks (Baena Preysler et al., 2010c). Multifacial cores predominate, and disaid and Levallois are absent. The presence of specimens aimed at obtaining supports for bifaces is remarkable. Retouched tools are scarce. With regard to the macro tools, which are poorly elaborated, use of old industries and flakes as support is frequent. The predominant categories are trihedral picks, followed by handaxes, cleavers on flakes and choppers. The trihedral picks, which have been compared to those from Tafesa (Baena Preysler and Baquedano, 2004), are small in size, no larger than 15 × 10 cm (Fig. 5). The handaxes, with a morphology next to that of the trihedral picks, are poorly executed, and have been made through non-alternating removals. The cleavers on flakes also show small sizes and are poorly executed, the Tixier’s O and I types being

Fig. 4. 1–4. Bifaces from level TGS at Puente Pino site in Alcolea del Tajo, Toledo (Spain); 5–8 Handaxes from level PNA at Puente Pino. 7 and 8 are knapped on flake.
dominant. Finally, the choppers, which are hardly distinguished from the cores (Baena Preysler et al., 2010a) were made through opposite removals that form pointed edges.

Downstream from Talavera de la Reina, in the T +30 m, several Acheulean assemblages have been identified. Nearly 30 pieces were found in Dehesa de Cobisa (Calera y Chozas), including unretouched flakes, five cores, several trihedral picks, one chopper and a partial handaxe (Rodríguez de Tembleque, 2008). In Peraleda de la Mata and in the surroundings of Puente de Los Mármoles, some Levallois pieces, handaxes and cleavers on flake have been recorded.
nodule, just like the cleavers on (Ollédavadra et al., 2010), as well as wear traces on some lithic pieces although cut marks have been recorded on some bone surfaces.

Two sites in Arídos 1 and Arídos 2. With regard to the lithic tools, among the chaînes opératoires of débitage, the low representation of discoids and the prevalence of less elaborate exploitation schemes such as unipolar and bifacial schemes is remarkable. The high presence of cortex in the quartzite flakes suggests a predominance of short lithic chaînes opératoires, typical of unipolar exploitation of some bone pieces on flakes, among which no complex types have been recorded, show single retouch types. The flint flakes are slightly more retouched than those from quartzite, just as occurs at bifaces. The chaînes opératoire de façonnage, are dominated by choppers, followed by handaxes and tridihedral picks, and to a lesser extent by cleavers on flake. More than half of the handaxes are partial, most of them knapped on a flake, and the remaining show amygdaloid silhouettes. The bifaces on flint flake, which are probably imported, are larger in size than those made from quartzite. The tridihedral picks are briefly elaborated, their final shape adapted to the original nodule, just like the cleavers on flake, which are of the 0 and I types.

Two paleo-surfaces were distinguished in Arídos 1, where 112 m² were excavated (Santonja et al., 1980). In the lower surface, 328 lithic pieces were found associated with the disarticulated and incomplete remains of one single specimen of E. (Paleoloxodon) antiquus. The site was interpreted as a butchering site. Nearly three quarters of the lithic assemblage consists of debris and fragments, mainly flint, and the rest are flake, tools, and macrotools, suggesting that part of the industry was knapped in situ. Most pieces are flint, only 4% quartzite and just 1% quartz. Hammerstones and choppers were made of quartzite, whilst nearly all the retouched tools were made of flint, as well as the cores —except for one very large example handaxes. There are two Levallois cores and six Levallois flakes. Among the retouched tools, the lack of scrapers and notches is outstanding, as well as the high number of burins showing traces of having been sharpened on different occasions. The handaxes are represented only by two distal fragments, and several flakes of resharpening, which suggest that these tools were introduced already manufactured and were resharpened on site (Santonja et al., 1980).

200 m from Arídos 1, the remains of E. (Paleoloxodon) antiquus were found together with 34 lithic pieces at Arídos 2 (Santonja and Querol, 1980). The central portion of the skeleton was found anatomically connected in the preserved 12 m² of the site. The remains were lying over an old floodplain surface, covered and partially eroded by gravel and sand deposits. The relationship between the industry and the elephant is not as clear as in Arídos 1, although cut marks have been recorded on some bone surfaces (Vavra et al., 2010), as well as wear traces on some lithic pieces (Ollé, 2005). The industry is mainly made of flint, except for two flakes and the macrotools of quartzite. Nearly half of the pieces are débitage and fragments, suggesting that at least part of the flint was knapped there, although the chaînes opératoires are not complete. There are no Levallois among the flakes and only a few are retouched. The bifaces consist of a handaxe with lanceolate ficon silhouette, and a cleaver on flake similar to Tixier’s II type. The lack of flakes and débitage suggests that these pieces had probably arrived on site already configured.

In the San Isidro hill, in Madrid, located in the T +25–30 m of the Manzanares valley, discoveries of E. (Paleoloxodon) antiquus with faunal associations belonging to the Middle Pleistocene (Sese and Soto, 2002), and Acheulean industry have been unearthed since the middle of the 19th century. As is usual in the Manzanares valley, the industry is mainly made of flint. The only available detailed study is the one carried out on 191 handaxes (Santonja, 1977), in which two assemblages were distinguished; one consisting of thick amygdaloids, relatively symmetrical, and the other consisting of better made handaxes, retouched with soft hammerstone, among which the cordiform, lanceolate and ovoid types were frequent (Santonja, 1977). Recently a flint tridihedral pick and a quartz chopping-tool have been recorded on this hill, as well as a unipolar core on quartz flake, an un-retouched flake and a fragment of a quartzite tool (Gómez Hernández et al., 2005).

In the Transfesa site, located in the same terrace 7 km downstream from the San Isidro hill, the remains of two male adults of Elephas (P) antiquus were recorded in the 1950’s (Meléndez and Aguuirre, 1958). These remains were lying on a level of fluvial gravels covered by associated gravel and marl, which probably would have formed part of an abandoned meander (Santonja et al., 2001). Remains of suidae, cervidae and equines were also found. In this same level (Quero Castro, 2002) the presence of lithic industry has been noted (Andres and Aguirre, 1974), although it is not possible to establish a relationship between the lithic tools and the faunal remains. A total 163 lithic pieces come from the basal gravel (Cacho and Martos, 2002). Among these, there are plenty of thick asymmetrical handaxes, of abbevillian and amygdaloid types, as well as retouched flakes and amorphous cores (Rus, 1989).

In 1996 a new site, named Tafesa, was excavated close to that site (Baena Preysler and Baquedano, 2004; Baena Preysler et al., 2010a). Silva et al. (2010) locate the site in what they call TCMZ (T9) o T +22 m of the River Manzanares, even though it has traditionally been assigned to the stepped terrace +25–30 m (Goy et al., 1989), as can be inferred looking at the topography of the valley. The lithic assemblage of this site can be compared to those recorded from sites at the middle terraces of the River Tagus, located +25–30 m from Pinedo or Cien Fanegas. An area 100 m² was excavated on an old floodplain crossed by drainage channels (Silva et al., 1997). Remains of Elephas (P) antiquus, Bos, mid-sized deers, Megaloceros savini, and Oroctolagus cuniculus were recorded (Sese, 2010), together with 651 lithic pieces arranged in four levels. 464 of those pieces were recovered from level IV, in an area only 30 m² (Baena Preysler and Baquedano, 2004; Baena Preysler et al., 2010a). With regard to the lithic industry, there is a minor use of quartzite and quartz versus flint. The use of old industries as blanks has been recorded in the configuration of both macrotools and cores. The high presence of cobbles is remarkable (36%), although only six of them show percussion marks (Baena Preysler et al., 2010a; Cuartero, 2010). Macro tools, which consist almost 20% of the total, are also well represented, as well as other tools, which reach values higher than 30%. The flake production is focused mainly on bifacial and multiface operative schemes, and to a lesser extent on orthogonal and discoid schemes, with no presence of Levallois (Baena Preysler et al., 2010a), suggesting an expeditious assemblage. Among the tools on flake denticulates are dominant, followed by scrapers, notches and becs (Baena Preysler et al., 2010a). There are no choppers among the macro tools. There are only two cleavers on flake, in contrast with the 22
handaxes and trihedral-picks present, which are thick, with sinuous edges and barely symmetrical profiles (Fig. 5). The presence of débitage, hammerstones and some refits suggests the knapping was carried out on site.

3.2.3. Terrace +23–24 m

Only data from the Jarama valley are available for this terrace level. In Las Acacias 114 pieces were retrieved from near the base of a section where fragments of Elephas tusks were recorded (Santonja and Querol, 1977). The raw material is mainly quartzite, and in a very low proportion, flint. The unifacial and bifacial types dominate among the cores, and there is one similar to a Levallois. The most common tools on flake are scrapers, which show deep and regular retouch (Santonja, 1981a), followed by natural backed knives and Mousterian points. Macro tools represent more than one third of the assemblage, including plentiful choppers, handaxes and cleavers on flake, whereas trihedral picks are barely represented. Both flat and thick handaxes are equally present, the cordiform, amygdaloid and protolimande silhouettes being notable. Among the cleavers on flake, those made on an ordinary flake or II type are dominant, followed by the 0 type, with generally sinuous edges.

The site of Valdocarros, where the largest extension of an Acheulean site has ever been excavated in the Iberian Peninsula after Torralba and Ambrona, is located to the upper third of the Arganda II stratigraphical unit 

\( = T + 23–24\) m. Three sedimentary episodes have been recorded, which have been named, from bottom to top, I, II and III. Valdocarros I and III consist of wide floodplains away from the main course. Valdocarros II consists of an abandoned meander integrating two different sedimentary environments; one towards the bottom, with gravel deposits and sand in channel facies eroding Valdocarros I, and another one consisting of a silty-clay and sand fill in which four levels 30–50 cm thick containing lithic industry and faunal remains have been distinguished. In Valdocarros I, 18 m² have been excavated, and 836 m² in Valdocarros II (Fig. 6). The association of reptiles and amphibians recorded in levels 2, 3 and 4 of Valdocarros II suggests a quick climatic shift. This could be matched with the transition between MIS 8 and MIS 7 (Blain et al., 2012). The faunal remains are fragmented, disarticulated and show a similar distribution to that of the lithic industry. Among the 2750 remains of large mammals retrieved, Elephas elaphus is the best represented species, followed by Equus caballus, Bos primigenius and to a lesser extent Capreolus sp., Dama sp., and Elephas sp. (Yravedra and Domínguez-Rodrigo, 2009). A small amount of carnivorous remains must be added to this assemblage (Felis sp., Canis lupus and Vulpes vulpes). Nearly two thirds of the lithic assemblage consists of flint pieces, a third of quartzite and the rest is quartz. Flint is mainly used for flake production, whilst quartzite is used for both flakes and macrotools. Scarcely elaborated quartzite cores predominate within the identified operative schemes (unifacial, bifacial, and to a lesser extent, jano), as opposed to discoids. The bifacial, multifacial and discoid types dominate among the flint cores. Only one Levallois core has been recorded, although several flakes have been obtained by this method. The retouched tools have been knapped mainly on flint, whether on flakes, cores or even old industries. The best represented morphotypes are denticulates, retouched flakes, scrapers and backed knives. Awls and burins have also been recorded. Most of bifaces are handaxes, followed by cleavers on flake, whilst trihedral picks are barely represented. Most handaxes have been made from quartzite, and some from flint (Figs. 7 and 8). Many of them have been adapted to the shape of the support, showing few removals, especially in the case of flakes and old industries used as blanks. All cleavers on flake are quartzite and 0 or 1 types, characterised by the edges being arranged with only few removals (Fig. 8). Most choppers are quartzite, some flint and quartz in one case, showing unifacial simple edges, and to a lesser extent simple and double bifacial edges.

3.2.4. Complex Terrace of Butarque (CTB)

Several Acheulean lithic assemblages have been found at the visible base of the initial trench of this terrace, which can reach up to 70 m in thickness (Uribelarrea, 2008). The chronological data can only point to its position within the Middle Pleistocene (Laplana et al., 2015), as it is not possible to specify whether it falls in MIS 7 or MIS 6.
A total of 4921 pieces were found at the Santa Elena sand quarry (Cacho and Martos, 2002; Gamazo, 2002), matching different units within the CTB, which were comprised since the final Middle Pleistocene to the early Upper Pleistocene. Acheulean and Middle Palaeolithic industries have been recorded, although the levels have not been distinguished so far. Bifaces are well represented in this assemblage, together with a substantial number of Levallois cores and a certain percentage of tools on blades, which are probably related to Upper Pleistocene deposits. Among the handaxes, lanceolate and micoquian specimens are plentiful. Trihedral picks show slender silhouettes, and those made on kombewa flake, Levallois and Tixier’s V type stand out among the cleavers on flake (Santonja and Querol, 1980). The faunal association of this sand quarry can be put down to the Middle Pleistocene, and comprises Elephas (P) antiquus, Rhinocerotidae indet., Equus caballus, Cervidae indet., Bovidae indet. cf. Bos/Bison (Sese and Soto, 2002).

A further faunal assemblage dated in the Middle Pleistocene was recorded at the Oxígeno sand quarry (Elephas (P) antiquus, Equus caballus, Cervidae indet., Bovidae indet. cf. Bos/Bison) (Sese and Soto, 2002: 448), where 10,416 lithic pieces were retrieved (Cacho and Martos, 2002; Gamazo, 2002). Within a series of 5000 pieces, mainly flakes and fragments, 219 handaxes were recovered, as well as 38 trihedral picks and 21 cleavers. Most of them are made of flint, and a few of quartzite (Rus and Querol, 1981). Most handaxes are made on flake. The thick ones are dominant (195), and include lanceolate-micoquian types, as well as amygdaloid and protolimandes; among the flat handaxes, cordiform, discoid and ovoid types stand out. The edges have been regularised or sharpened with a soft hammerstone. The best represented cleavers are of Tixier’s V, II, 0 and I types (1956), showing regular symmetric silhouettes, usually shaped with a hard hammerstone, which is also used for making trihedral picks, mainly on flake.

3.2.5. Interfluve between the Manzanares and Jarama rivers

The sites recorded at Los Ahijones are found on the dividing platform along the Manzanares–Jarama rivers valleys (Figs. 1 and 2). This is characterised by the presence of layers of flint and carbonated clay belonging to the Middle Miocene, which forms the headwaters of the main drainage net of the platform, consisting of Los Migueles stream (affluent of the River Manzanares), and its tributaries, Los Ahijones and El Cañaveral stream (Bárez et al., 2010). The sites recorded in this area are related to the primary outcrops of siliceous rocks, and to its reiterate use as source of raw materials (Baena Preysler et al., 2015). In terraces T1, T2 and T3 of Cañaveral, dated in the final Middle Pleistocene (T1 > 150 ka BP and 115 ± 32/– 19 ka BP for the edaphic horizon developed over T2, Bárez et al., 2010), nine Acheulean lithic assemblages have been found. There is a high percentage of handaxes, although cleavers on flake and trihedral picks are virtually absent.

Fig. 7. Handaxes on quartzite and flint from Valdocarros II site (Madrid, Spain).
The site of El Cañaverual (Baena Preysler et al., 2008a, 2008b, 2010b), has also been linked to the direct exploitation of siliceous outcrops, which favoured its exploitation during the Pleistocene, having been recorded in the same environment Acheulean and Mousterian lithic assemblages (Baena Preysler et al., 2008a,b). Several sub-categories concerning the exploitation of recycled material have been distinguished: old industries have been exploited, retouched or used as hammerstones, having used cores as hammerstones or vice versa (Baena Preysler et al., 2011, 2015).

4. Discussion

In the Tagus basin, the first evidence of the Acheulean techno-complex can be dated to the MIS 15–12 and certainly to MIS 11. If the Acheulean period entered Europe through the Strait of Gibraltar (Santonja and Villa, 2006; Santonja and Pérez-González, 2010; Moncel et al., 2016), the Tagus basin necessarily had to play an important role in its extension throughout Southern Europe. The valley of the river Tagus, along its 1007 km, connects the south of the Iberian Peninsula with the other two large basins of the Iberian Peninsula, the Duero and the Ebro basins.

No site has been excavated in the Tagus basin with a date prior to MIS 13. The small number of lithic finds referable to this period are located in the middle and high terraces of the Tagus valley and in some of its tributaries. In this valley, in the T +105 m and T +83 m, there is evidence of human presence with dates older than one million years. This comes from a relative date of the terrace deposit in which poor assemblages of lithic industry have been found, with no diagnostic specimens which would allow them to be assigned to a particular techno-complex (Santonja and Pérez-González, 1997; Rodríguez de Tembleque et al., 2010). In the River Arlanzón valley, in the Duero basin, the terrace +70–78 m with normal polarity (Benito-Calvo et al., 2008), and dated by ESR to 1.140 Ma (Moreno et al., 2012), may represent the normal Subchron Jaramillo (0.990–1.070 Ma; Pérez-González et al., 2013).

The oldest evidence of the Acheulean occurs in a terrace located at 70 m relative height, where a biface on flake was found. This could date the beginning of this techno-complex to the end of the Lower Pleistocene, although new discoveries of greater importance may well take place. The evidence is more solid in T +40–45 m at Hornaguera and Paridera, (Santonja and Pérez-González, 1997; Rodríguez de Tembleque, 2008). These terrace levels may correspond with MIS 15–12, considering that terrace +50–55 m (Panera et al., 2011) could be as old as 0.7–0.6 Ma according to the ESR dates of this terrace level at the Arlanzón valley, in the Duero basin (Moreno et al., 2012), and the date 292 ± 17 ka, obtained by IRSL in the T +25–30 m of the Tagus valley (López-Recio et al., 2015). Puente Pino could be the oldest Acheulean site excavated in the Tagus basin, taking into consideration that PNA could fill an intermediate position between the terraces +40–45 m and +30 m of the regional fluvial sequence of the River Tagus (Rodríguez de Tembleque, 2004, 2005a, 2008).

Acheulean lithic assemblages become common from level +30 m, as has been revealed in the unit Arganda I = T +30–32 m of the Jarama valley, and the T +25–30 m of the Tagus and Manzanares valleys. From this moment on, Acheulean assemblages have been recorded in the valleys of the main and secondary rivers of the Tagus basin. The T +25 m has been dated to the MIS 11–13 (Sese and Soto, 2000; Mazo, 2010). Arganda I to the end of MIS 11 or early MIS 9 (Panera et al., 2011), and the T +25–30 m of the Tagus valley to the final MIS 9 or early MIS 8 (López-Recio et al., 2015).
Valdocarros, in the unit Arganda II of the CTA (≈ T + 23–24 m), is the excavated Acheulean site which provides a late date, between MIS 8 and MIS 7 (Panera et al., 2011; Blain et al., 2012). Lithic industry assemblages have also been recorded in secondary positions in the Arganda II gravel bars.

The latest evidence of the Acheulean technocomplex in the Tagus basin could be located at the T + 18–20 m and in the visible base of the CTB initial stretch, in the Manzanares valley, which date to the final Middle Pleistocene (Laplana et al., 2015). The materials ascribed to the Acheulean found in the Manzanares and Jarama interfluvie have also been ascribed to this time (Bárez et al., 2010; Baena Preysler et al., 2015).

Fluvial loads have been influential in the choice of raw materials used for manufacturing lithic tools, but not decisive. Thus, in the Tagus and Jarama valleys, where there is plenty of quartzite, the chaînes opératoires de façonnage, particularly those set aside for production of choppers and cleavers, are better represented than in the Manzanares valley, where flint predominates and quartzite is absent. Nevertheless in this valley manufacturing of bifaces on flake is frequent. Then again, in the in situ sites of the Jarama valley, flint pieces are frequent in the chaînes opératoires de débitage, despite being a rare raw material. This could be interpreted as the requirement to the functioning of the sites, or else flint was preferred for knapping tools on smaller flakes.

There is little information about some levels of terraces, particularly the highest and the lowest. Besides, this information often comes from old research and publications, making it difficult to elicit general conclusions.

With regard to macro tools, handaxes, often knapped on large flakes, are the most frequently recorded tools, followed by choppers, while cleavers and trihedral—trihedral picks are less represented. Among the handaxes, thick, asymmetrical, rough types are dominant, with irregular edges and barely retouched. Nevertheless, more carefully elaborated and balanced specimens are also found, such as those from San Isidro and Las Acacias (Santonja, 1977; Santonja and Querol, 1977). The most frequent cleavers on flake are of Tixier’s type 0 and, to a lesser extent, type 1 (Tixier Inzain, 1956). With regard to the cores, the predominant chaînes opératoires are bifacial and polyhedral, followed by discoid, which are normally well represented. Levallois cores are exceptional. The most common retouched tools on flake are scrapers, followed by denticulates. More elaborated types such as awls and, particularly, end-scrapers, are scarce.

The main source of information for the characterization of the lithic industry of the final Middle Pleistocene is the Manzanares valley, specifically from T + 18–20 m and from the visible bottom of the CTB, and also old research of poorly published lithic assemblages. Flint is the predominant raw material due to the lack of quartzite in the load of this river. These deposits contain the last clearly Acheulean evidence. The chaînes opératoires de façonnage, with meagre percentages, are almost exclusively represented by handaxes and to a lesser extent by cleavers on flake and trihedral picks, choppers being totally absent. Handaxes continue being manufactured frequently on large flakes, although thick ones are still predominant. Their silhouettes tend to be well balanced and symmetrical, and the edges regularized or resharpended by retouch, although poorly elaborated edges are also present. As for the cleavers, regular silhouettes are also common. Tixier’s types V and II are predominant, followed by types 0 and I. Flakes have not usually been detached from the cores in a preconceived manner. Discoid types are not always present, and when they are, it is in low percentages. The most common cores are non-organized and with a low number of removals. With regard to the retouched tools, scrapers and denticulates are predominant, although all types described by Bordes (1961) are present.

The basic differences between the lithic assemblages recorded on the one hand in the terraces +30 m and +23–24 m, and on the other hand in the terrace +18–20 m, lie, above all, in the configuration of the chaînes opératoires de façonnage, particularly in the case of the handaxes, as choppers have hardly been described, and the percentage of cleavers on flake and trihedral picks is inferior in the lower terrace. Higher percentages of well-made handaxes, well-balanced and symmetrical, with edges regularized or resharpended by retouch have been recorded in this level. Cleavers on flake show regular silhouettes, and Tixier’s types V and II are predominant. A certain rise of the complex types can be observed among the retouched tools, although scrapers and denticulates continue to dominate the sample. However, clear differences cannot be established in the chaînes opératoires de débitage. The most common cores are elemental and without an organized exploitation scheme. Discoids cores are uncommon, and Levallois cores are scarce.

The Acheulean assemblages found in the interfluve between the Manzanares and Jarama rivers, associated with primary flint outcrops, are characterized by a high percentage of handaxes, and an almost total lack of cleavers and trihedral picks (Baena Preysler et al., 2008a,b; Bárez et al., 2010).

In the Iberian Peninsula, the Middle Palaeolithic has been recorded since MIS 10/9 in sites such as Ambrona, Cuesta de la Bajada or TD 10 in Atapuerca (Rubio-Jara, 1996; Santonja and Pérez-González, 2006; Olle et al., 2013; Santonja et al., 2014), coexisting with Acheulean sites, such as Torralba and Valdocarros (Santonja et al., 2016). There is conspicuous evidence of the Middle Palaeolithic during MIS 5 in the Jarama and Manzanares valleys (Panera et al., 2005; Pérez-González et al., 2008), and even probably since the final Middle Pleistocene, although the timeframe cannot be accurately specified (Panera, 2009; Rubio-Jara, 2011). In the Manzanares valley and in the interfluve between this and the Jarama river, lithic assemblages with a practical dearth of cleavers on flake, trihedral picks and choppers are recorded, containing bifaces-tool support (Boeda, 2001), and with a stronger Levallois presence (Bárez et al., 2010; Rubio-Jara, 2011; Baena Preysler et al., 2015). This could be the result of the relation between the Acheulean and EAMP, as pointed out by Santonja et al. (2016). More accurate timeframes and detailed techno-economic descriptions of these lithic assemblages are necessary for their understanding and characterization.

Many Acheulean lithic assemblages have been found in gravel or sand bars (Pinedo, Cañete, La Gavia I, Santa Elena, Oxigén). As a result, the remains have been moved from their original location and may come from other spots where different activities were carried out. This type of site provides techno-economic information, whereas sites found on overbank facies (Arídos 1 y 2, San Isidro, Valdocarros, Transfesa and Tafesa), have optimal preservation of the spatial relationship of the remains, and also provide information regarding how the human groups adapted to the fluvial ecosystems.

Several sites with remains of E. (Paleoloxodon) antiquus associated with lithic industry are known in the terrace +25–30 m (San Isidro, Orcasitas, Transfesa and Arídos 1 y 2; Santonja et al., 2001), although they are old findings, incompletely recorded, except for Arídos 1 and 2. Remains of proboscidea dating between MIS 6 and MIS 5 have been recorded in 17 sand quarries at the CTB in the Manzanares valley, and in at least four cases interaction between hominins and megafauna were proven (Panera et al., 2014). There are more Lower Palaeolithic sites than Middle Palaeolithic known in Europe, where exploitation of proboscideans has been proved. However, the findings recorded from the Manzanares valley reveal that there were no important changes in the subsistence strategies with regard to these mammals during the Acheulean and the Middle Paleolithic.
The sector PNA of Puente Pino has been interpreted as a site where human groups manufactured and used lithic tools in unspecific activities, based on the presence of complete lithic chaînes opératoires, and the concentration and diversity of industry and tools (Rodríguez de Tembleque, 2008). The strategic location of the site, the record of different archaeological levels and the presence of several Acheulean sites in the surroundings suggest that the area was recurrently visited by human groups (Ruiz Zapata et al., 2009). In Tafesa (Baena Preysler and Baquedano, 2004), presence of knapping remains, hammerstones and some refits suggests knapping being carried out on site. According to cut marks identified on diaphysis of large mammals, knapping would be related, at least in part, to meat consumption (Yravedra, 2010).

The site that gives more information about the interaction between human groups and the environment is Valdocarros. The abandoned meander of Valdocarros II was occupied at least on four different occasions and under different climatic conditions. The human groups went back several times, probably attracted by the abandoned meander and the dense vegetation. The hominins were the main agent of accumulation of vertebrate remains, moving the carcases from short distances (Yravedra and Domínguez-Rodrigo, 2009). In Valdocarros II, knapping has been related mainly with core reduction, and in some levels with handaxe shaping and resharpening. Most sites excavated in the Iberian Peninsula to date correspond to specific activities, such as exploitation of large mammal carcases or knapping lithic tools. Valdocarros, which presents one of the largest areas with Pleistocene archaeological remains of the Iberian Peninsula, is a different case.

With regard to raw material collection, the Jarama and Tagus valleys have yielded plenty of quartzite and quartz cobbles, whereas the primary flint outcrops from the Manzanares-Jarama interfluve have been recurrently exploited since the final Middle Pleistocene (Bárez et al., 2010; Baena Preysler et al., 2015).

Acheulean sites with middle to high industrial density have also been described from deposits developed on high terraces, +50 m or more, as well as middle ones, sometimes on alluvial fans (Rodríguez de Tembleque, 1997; Panera, 2009). Despite lacking a timeframe, these lithic assemblages allow the exploration of the spatial frame of the Acheulean groups, beyond the activities carried out on the floodplains (Díez-Martín et al., 2008).

5. Conclusions

Practically all the Acheulean sites have been recorded in fluvial terraces, which has limited all the available information to this sedimentary environment. This is due to the ability of this environment to generate and preserve deposits, plus the subsistence potential which characterises Mediterranean fluvial valley ecosystems, which constituted authentic ecological corridors, making the faunal circulation between different geographic areas and ecosystems easier. Other morphosedimentary environments present in the basin, such as karstic, have not been subject of systematic research, and could yet give relevant information on the topic.

Despite lacking an accurate timeframe, the first Acheulean evidence could be dated to between MIS 15 and 13. In accordance with the numerous lithic assemblages found in stratigraphical contexts and by the sites excavated in T +30 m, from MIS 11 on, at most MIS 9, this techno-complex is widely spread throughout the Tagus basin. Valdocarros (~T+23–24 m), ascribed to MIS 8/7, is the most recent Acheulean site excavated in the Tagus basin, and one of the most recent of the Iberian Peninsula. The final Acheulean evidence could be dated to MIS 6, in the T +18–20 m and in the visible bottom at the initial stretch of the CB at the Manzanares valley.

As in the case of the African Acheulean, and the rest of the Iberian Peninsula and Southern France, the chaînes opératoires are present in significant percentages, and the use of large flakes for shaping bifaces is common, although the available raw materials have an influence on their representativeness. Handaxes, often made on flake, are the most common bifaces. They tend to be poorly elaborated, with non-regularized or non-retouched edges. Trihedral picks are scarcely represented, and cleavers on flake are of 0 and 1Tixier’s types. With regard to the chaînes opératoires de débitage, short examples predominate in quartzite, and polyhedral and discoid in flint. Levallois presence is scarce. As observed from sites on overbank facies, there is a certain preference for flint for knapping small tools. Retouched tools are usually little elaborated. Scrapers and denticulates are the most characteristic morphotypes.

To the end of the Middle Pleistocene, in the Manzanares valley and in the interfluve with the River Jarama, lithic assemblages with chaînes opératoires de façonnage are present in the archaeological record, almost exclusively represented by handaxes. These handaxes are more elaborate than previous and their edges have been regularized by retouch. Cleavers on flake of Tixier’s V and II types are also included in these assemblages, as well as complex retouched tools on flake. Levallois cores are also present. These assemblages may respond to the interrelation between Acheulean and EAMP suggested by Santonja et al. (2016).

With regard to the adaptation of the human groups with Acheulean technology to fluvial ecosystems, the number of sites where proboscidean remains have been found associated with lithic industry is outstanding. This is also recorded during the Middle Palaeolithic, unlike in other European regions, and should be analysed under the relations which occurred between these techno-complexes. In other sites, such as Puente Pino or Tafesa, we do not know the activities carried out by the hominins, beyond manufacturing lithic tools. Evidence from Valdocarros has shown for the first time an occupation site where human groups went at different occasions and under different climatic conditions; where lithic tools were brought, as well as raw materials for manufacturing new ones; and where parts of large mammals carcases were exploited using these tools. The activities of human groups with Acheulean technology were developed beyond the floodplains, according to the lithic assemblages found on the middle terraces, higher than +50 m, and by the primary flint outcrops in the Jarama-Manzanares interfluve, which have been recurrently exploited since the end of the Middle Pleistocene.

Acknowledgements

We would like to express our gratitude to the editors for inviting us to participate in this special issue; to the Dirección General de Patrimonio Histórico de la Comunidad de Madrid and Diputación de Toledo for financing the excavation works at Valdocarros and Puente Pino sites; and to Marta Muniz and Ciara Travers for English editing. We are also grateful to the two anonymous reviewers for their careful work and useful remarks.
